Stat405 Final Project
Aiwei Yang 42274209
Chang Sun 19062439

Aiwei Yang primarily focused on data processing, EDA and visualization. Chang Sun was mainly responsible for model implementation in Stan including both HMC and VI methods. We jointly contributed to model design, final interpretation and writing the final report.

Part 1. Introduction

Bicycle renting systems are one of the popular modes of transportation used by individuals in urban areas owing to the convenience and environmental benefits involved. Therefore, there is a need to have adequate knowledge about the various determinants of bicycle rental demand.

In the current research paper, a time series dataset is analyzed where the independent variables include weather and calendar related variables, while the dependent variable involves the number of bicycles rented.

This paper aims to identify and quantify the effects of weather and calendar-related factors on bike rental demand in the U.S. for the period 2018-2019.

Part 2. Data Description & Exploratory Analysis

Data Description:

This dataset contains daily data of bike rental demand with several variables that explain factors like weather and calendars. The dependent variable is total bike rentals (cnt), which shows daily demand for bikes.

The independent variables are categorized into three groups. These include weather variables temp (temperature), hum (humidity), and windspeed. The calendar variables include season, which indicates different seasons, workingday, which is an indicator of whether it is a workday or not, and holiday, which determines whether it is a holiday or not. yr is the variable that explains the trend over time.

Some variables are not considered in this study. The variable instant serves as an index, and thus, it cannot predict anything. Casual and registered variables are ignored since they sum up to the dependent variable cnt, hence violating the assumption of no perfect multicollinearity. Finally, between weekday and workingday, workingday is considered due to its simplicity.

Research Question:

Which weather and calendar-related factors are associated with daily bike rental demand?

Modelling Challenge:

First, the dependent variable is daily bicycle rental demand (*cnt*). It is a non-negative integer and falls under the category of count data. Hence, traditional linear regression analysis is not applicable since special models should be employed.

However, the problem becomes more complex due to variations in the data. In most cases, there will be more variation than expected based on the average demand value. For instance, the variance may be greater than the mean value. This situation leads to overdispersion of the data, which is contrary to the assumptions of the Poisson distribution model.

Thus, alternative approaches like using the negative binomial regression model are recommended. Another benefit of Bayesian methods is that uncertainties associated with the parameter estimates can be directly calculated.

Exploratory Data Analysis:

The daily number of bicycles rented covers a wide range, with most observations taking place in the interval between 2,000 and 7,000. Extreme values are not as common but still noticeable. Variability from day to day is quite considerable. There is a clearly visible positive correlation between temperature and rentals; higher temperatures correlate with greater demand, although there is still considerable dispersion among the data points. Humidity demonstrates a slight negative correlation with the number of rentals; demand drops as humidity grows, although the correlation is relatively weak. Wind speed correlates negatively with demand; as the wind gets stronger, the number of rentals decreases slightly. However, there is some variability present. Seasonal differences have proved to be rather significant. The demand is lower during the spring season, higher during the summer and autumn seasons, and more variable during the winter one. Working days and weekends demonstrate only minor differences; their distributions are quite similar. By comparison, holidays are characterized by lower demands, which can be seen by the overall drop in the distribution's position. Finally, there is a much higher demand in 2019 than in 2018. These patterns provide initial evidence of overdispersion and nonlinear variability in the data, motivating the use of more flexible count models such as the Negative Binomial specification.

Figure 1. EDA of selected variables

Model 1: Bayesian Poisson Regression Model

(1) Likelihood

Let cnt_i denote the number of bike rentals on day i. Since the response variable is count-valued and non-negative, we model it using a Poisson distribution:

$cnt_i \sim Poisson(\lambda_i)$

where the mean parameter λ_i is linked to the covariates through a log-linear model:

$log(\lambda_i) = X_i\beta$

Here, X_i represents the vector of explanatory variables, including weather and calendar-related features.

(2) Prior

To complete the Bayesian specification, we assign independent priors to the regression coefficients:

$\beta_j \sim N(0, 10)$

For the regression coefficients, we use normal priors centered at zero with moderate variance. This reflects the lack of strong prior knowledge while preventing unrealistically large effects from any single variable.

(3) Why Poisson

The Poisson model provides a natural starting point for modeling count data, as it directly captures the non-negative and discrete nature of the response variable. It also serves as a baseline model for comparison with more flexible alternatives, such as the Negative Binomial model.

Model 2: Bayesian Negative Binomial Regression

(1) Likelihood

Let cnt_i denote the total bike rental demand on day i. To allow for overdispersion in the count outcome, we consider a Negative Binomial model:

$cnt_i \sim NegBin(\mu_i, \phi)$

with mean parameter linked to the covariates through

$log(\mu_i) = X_i\beta$

where, X_i contains the selected weather and calendar-related variables, and is a dispersion parameter.

(2) Prior

We assign the same weakly informative priors to the regression coefficients:

$\beta_j \sim N(0, 10)$

and place a positive prior on the dispersion parameter:

$\phi \sim Gamma(0, 1)$

For the dispersion parameter in the Negative Binomial model, we impose a prior that ensures positivity and avoids extreme values. This helps stabilize estimation while still allowing the data to determine the level of overdispersion. While the prior on ϕ ensures positivity and regularizes the dispersion estimate.

(3) Why Negative Binomial

The Poisson model assumes that the conditional variance is equal to the conditional mean. For bike rental demand, this assumption may be too restrictive, since daily demand can vary substantially across days even under similar weather and calendar conditions. In such cases, the variance may exceed the mean, indicating overdispersion.

The Negative Binomial model relaxes this restriction by introducing an additional dispersion parameter. This makes it more flexible than the Poisson model and often more suitable for count data with extra variability.

(4) Comparison with Model 1:

This model extends the Bayesian Poisson regression by allowing the variance to exceed the mean. It is therefore expected to provide a better fit when overdispersion is present in the data. In the later model

comparison section, we compare the Poisson and Negative Binomial specifications to assess whether the additional flexibility leads to improved fit and predictive performance.

Literature review

A highly relevant study conducted by Xu (2024) analyses the same set of U.S. bike sharing data from 2018 to 2019 and uses multiple linear regression for daily demand prediction. The procedure includes data preparation, creation of dummy variables for categorical data, and using various methods, including variance inflation factor (VIF) and p-values for predictor selection. As a result, such indicators as temperature, year, and weather significantly affect bike demand.

On the contrary, the current research uses a Bayesian approach and applies Poisson and Negative Binomial regression due to the fact that the data belongs to counts. In addition, uncertainty analysis based on posterior distributions will be emphasized, and several regression models will be utilized in order to overcome overdispersion.

Posterior Inference Methods

HMC is used as the primary inference method, as it provides asymptotically exact samples from the posterior distribution and allows reliable uncertainty quantification.

VI is used as a faster approximation method. While it is computationally efficient, it may underestimate posterior variance and can introduce bias in parameter estimates. Comparing the two methods allows us to evaluate the trade-off between computational speed and inferential accuracy.

HMC: Hamiltonian Monte Carlo is the main technique used for estimating the posterior distribution. Hamiltonian Monte Carlo uses gradient-based proposal distributions to create posterior samples, and it is considered a better technique for conducting inference in this study. The posterior convergence for the Poisson distribution involves the values of 1.003341, 1529.346, and 1831.3, which are the highest value of $\widehat{R}$, lowest bulk effective sample size, and lowest tail effective sample size, respectively. Similarly, the posterior convergence for the negative binomial distribution involves the values of 1.004275, 1899.109, and 2758.454.

VI: The use of Variational Inference (VI) acts as a quicker approximate approach. In the case of the Poisson distribution, median ELBO convergence occurred after 3,700 iterations. Median ELBO convergence occurred after 1,300 iterations for the Negative Binomial distribution. VI is notably faster compared to HMC; however, it is only an approximation and not the inference solution itself.

Posterior Results and Converge Diagnostic

Both posterior calculations show consistency overall, and HMC diagnostic results support the usage of the posterior sample for analysis purposes. Four chains used in Poisson converge without any difficulties. The highest value of the Gelman-Rubin statistic is 1.003341, whereas the lowest bulk and tail effective sample sizes are 1529.346 and 1831.3, respectively. For the negative binomial model, the metrics equal 1.004275, 1899.109, and 2758.454. Such results indicate appropriate mixing of chains, which means that the posterior sample size is more than enough to capture the parameter set.

Although the Negative Binomial fit reports warnings during warmup, these occur sporadically at early proposals and do not persist in the final posterior diagnostics. Since the final $\widehat{R}$ values remain close to 1 and the effective sample sizes are large, the final HMC fit is still judged to be reliable.

To illustrate mixing directly, the traceplots for selected coefficients and the dispersion parameter from the Negative Binomial model are shown below. The traceplots show good

mixing across chains with no visible trends, indicating that the HMC sampler has converged and is exploring the posterior distribution effectively.

Figure 2. Traceplots for selected parameters under the Negative Binomial HMC fit

Posterior Predictive Checks and Model Fit

Posterior predictive checking methods are used to determine how well the models fit the distribution of bike rentals per day. Both models have an accurate representation for the mean. The mean of the observations is 4508.007; on the other hand, it is 4508.043 for the Poisson model and 4555.502 for the Negative Binomial model. The main difference between the models and the observations is in variance. The observed variance is 3,748,141; however, for the Poisson model it is 3,143,307, and for the Negative Binomial model – 5,731,131.

Figure 3. Posterior predictive density overlay under the Poisson model Figure 4. Posterior predictive density overlay under the NB model

The posterior predictive plots highlight clear differences between the two models. Under the Poisson specification, the replicated distributions display a much heavier right tail and a wider spread than the observed data. The simulated densities extend far beyond the range of the empirical distribution, indicating that the model generates unrealistically large values. In addition, the overall shape of the predictive distribution does not align well with the observed central mass. This suggests that the Poisson model fails to capture both the variability and the distributional shape of bike rental demand.In contrast, the Negative Binomial model produces predictive distributions that are much closer to the observed data. The central mass, overall shape, and range of the replicated distributions align more closely with the empirical distribution. The model is able to better accommodate the variability in the data, particularly

by reducing the excessively long tail observed under the Poisson model. However, some discrepancies remain, especially in the tails, where the model still slightly overestimates variability.

Overall, these posterior predictive checks indicate that the Poisson model provides a poor fit to the data, while the Negative Binomial model offers a substantial improvement by accounting for overdispersion, although it does not perfectly reproduce all features of the observed distribution.

Comparison of HMC and VI, Limitations and Conclusions

The comparison between HMC and VI demonstrates that the latter produces a considerably shorter calculation time regardless of the selected specification. In particular, VI requires 0.763 seconds for the Poisson model and 0.965 seconds for the Negative Binomial, while HMC consumes 1.809 and 6.043 seconds, correspondingly. At the same time, VI produces smaller posterior standard deviation values, indicating possible underestimation of posterior uncertainty. Although posterior means appear to be roughly equal, HMC seems to be more advantageous since it provides a full posterior sampling as opposed to VI.

Posterior predictive checks have been used to examine the adequacy of the fitted models. As can be seen from Figure 3 below, the Poisson model cannot explain variability and shapes of the data, while the Negative Binomial model explains the data significantly better due to consideration of overdispersion. However, it does not perfectly match the distribution of the observed data.

It is necessary to note several caveats of this analysis. First of all, there can be no causality inferred from the results. Secondly, some relevant variables have not been considered. Finally, despite a relatively good match, the Negative Binomial model still does not capture the data-generating process in its entirety since posterior predictive checks reveal some residual differences.

Overall, one can state that taking into account overdispersion when developing models for analyzing count data is crucial to avoid incorrect conclusions and unrealizable prediction. The use of the Bayesian approach has proved to be successful; moreover, the Negative Binomial model captures data much better than the Poisson model.

```

3. Prepare data for Stan

```r
stan_data <- list(
  N = nrow(X),
  K = ncol(X),
  y = bike_clean$cnt,
  X = X
)

stan_data$N
```

```
## [1] 730
```

```r
stan_data$K
```

```
## [1] 10
```

```r
head(stan_data$y)
```

```
## [1]  985  801 1349 1562 1600 1606
```

4. Remove old stan file if they exist

```r
if (file.exists("poisson_model.stan")) file.remove("poisson_model.stan")
if (file.exists("negbin_model.stan")) file.remove("negbin_model.stan")
```

5. Write Poisson Stan model

```r
poisson_code <- "
data {
  int<lower=1> N;
  array[N] int<lower=0> y;
  int<lower=1> K;
  matrix[N, K] X;
}
parameters {
  vector[K] beta;
}
model {
  beta ~ normal(0, 2.5);
  y ~ poisson_log(X * beta);
```

```
}
generated quantities {
  vector[N] log_lik;
  array[N] int y_rep;

  for (n in 1:N) {
    log_lik[n] = poisson_log_lpmf(y[n] | X[n] * beta);
    y_rep[n] = poisson_log_rng(X[n] * beta);
  }
}
"

writeLines(poisson_code, "poisson_model.stan")

# Verify the file contents
readLines("poisson_model.stan")
```

```
##  [1] ""
##  [2] "data {"
##  [3] "  int<lower=1> N;"
##  [4] "  array[N] int<lower=0> y;"
##  [5] "  int<lower=1> K;"
##  [6] "  matrix[N, K] X;"
##  [7] "}"
##  [8] "parameters {"
##  [9] "  vector[K] beta;"
## [10] "}"
## [11] "model {"
## [12] "  beta ~ normal(0, 2.5);"
## [13] "  y ~ poisson_log(X * beta);"
## [14] "}"

# Extract posterior predictive draws
yrep_poisson <- as_draws_matrix(fit_poisson_hmc$draws("y_rep"))
yrep_nb <- as_draws_matrix(fit_nb_hmc$draws("y_rep"))

# Posterior predictive density overlay
ppc_dens_overlay(y = bike_clean$cnt, yrep = yrep_poisson[1:100, ])
```

```
ppc_dens_overlay(y = bike_clean$cnt, yrep = yrep_nb[1:100, ])
```

```r
# Compare observed and replicated mean and variance
ppc_stats <- data.frame(
  model = c("Observed", "Poisson_HMC", "NB_HMC"),
  mean = c(
    mean(bike_clean$cnt),
    mean(rowMeans(yrep_poisson)),
    mean(rowMeans(yrep_nb))
  ),
  variance = c(
    var(bike_clean$cnt),
    mean(apply(yrep_poisson, 1, var)),
    mean(apply(yrep_nb, 1, var))
  )
)

ppc_stats
```

```
##         model     mean variance
## 1    Observed 4508.007  3748141
## 2 Poisson_HMC 4508.043  3143307
## 3      NB_HMC 4555.502  5731131
```

18. Save all summary tables

```r
write.csv(as.data.frame(poisson_hmc_summary), "poisson_hmc_summary.csv", row.names = FALSE)
write.csv(as.data.frame(poisson_vi_summary), "poisson_vi_summary.csv", row.names = FALSE)
write.csv(as.data.frame(nb_hmc_summary), "nb_hmc_summary.csv", row.names = FALSE)
write.csv(as.data.frame(nb_vi_summary), "nb_vi_summary.csv", row.names = FALSE)

write.csv(comparison_poisson, "comparison_poisson.csv", row.names = FALSE)
write.csv(comparison_nb, "comparison_nb.csv", row.names = FALSE)
write.csv(ppc_stats, "ppc_stats.csv", row.names = FALSE)
```

19. Compare computation times

```r
fit_poisson_hmc$time()
```

```
## $total
## [1] 1.809298
##
## $chains
##   chain_id warmup sampling total
## 1        1  0.669    1.005 1.674
## 2        2  0.587    0.929 1.516
## 3        3  0.580    0.912 1.492
## 4        4  0.581    1.028 1.609
```

```r
fit_poisson_vi$time()
```

```
## $total
## [1] 0.7630591
```

```r
fit_nb_hmc$time()
```

```
## $total
## [1] 6.042777
##
## $chains
##   chain_id warmup sampling total
## 1        1  2.307    2.640 4.947
## 2        2  2.231    2.491 4.722
## 3        3  2.502    3.501 6.003
## 4        4  2.011    2.439 4.450
```

```r
fit_nb_vi$time()
```

```
## $total
## [1] 0.9646602
```
